Summary

Innovations are generally unexpected, often spectacular evolutionary and developmental changes in phenotypes and ecological functions. The contributions to this special issue are the latest conceptual, theoretical and experimental developments, addressing how ecology, environment, ontogeny and evolution are central to understanding the complexity of the processes underlying innovations. Here, we set the stage by introducing and defining key terms relating to innovation and discuss their relevance to biological, cultural and technological change. Discovering how the generation and transmission of novel biological information, environmental interactions and selective evolutionary processes contribute to innovation as an ecosystem will shed light on how the dominant features across life come to be, generalize to social, cultural and technological evolution, and have applications in the health sciences and sustainability.

A central feature of life is change. Change may be rapid, such as a population crash during a disease epidemic or the evolution of antibiotic resistance. Change may also be slow, a prime example being the evolution of novel biochemical pathways leading to altered **phenotypic traits**, possibly generating new species. Both rapid and slow change can occur at the level of the genotype, the phenotype, as well as in ecological aggregates such as populations and communities. Its magnitude ranges anywhere from imperceptible and difficult to quantify, to highly visible and transformational, impacting not only individuals and their interactions but also their biotic and abiotic environments. **Innovations** comprise a class of changes that signal an often *a priori* unexpected departure from a previous state (see Glossary for definitions of this and other terms). Many of the conceptual foundations of innovation can be traced at least back to Darwin [1,2], who suggested that novelties could emerge either through natural selection or the co-opting of traits originally used for other functions. His ideas presaged some current concepts of innovation.

Innovations are important to understand because they are distinctive, apparently improbable changes to the phenotype, and yet pervade biology, culture and technology. Innovations are central to the evolution of complexity, phenotypic diversity, and to the construction and filling of new niches. Insights into the processes creating and spreading innovations are not only central to understanding life, but also for predicting the future of human society and natural ecosystems, such as the evolution of technologies, the impacts of medical breakthroughs on human demography, and the effects of global change on resource sustainability and species persistence. The growth of innovation research is evidenced by a keyword search of articles published in ecology or evolution between 1997 and

2017¹, which yielded an approximate fourfold increase in the fraction of articles using the keyword “innovation” (currently about 1%).

The aim of this theme issue is to present our current understanding of innovations and the innovation process across a spectrum of systems and organisational levels, with the ultimate objective of advancing a theory of innovations. Each of the papers of this theme issue articulates with the steps in the innovation process depicted in Figure 1 or the patterns they produce. Although the focus of most of the contributions in this special issue is biological, given that ecological and evolutionary processes influence human culture, society, economics and technology, the insights emerging could contribute to a theory that encompasses complex behavioural systems, and be transferrable to applications in the biological and social sciences, ranging from conserving biodiversity to managing pathogens, pests, and invasive species, to understanding the growth of cities, economies, and technologies. Therefore an important objective of this theme issue and the discussion below is to better understand the commonalities and contrasts of innovation in biology, culture and technology.

What is an innovation?

Innovation and the related concepts of invention and novelty have been extensively discussed in the biological [3] and social sciences [4]. Given the many disciplines and systems to which innovations matter, a diversity of definitions is not surprising [5]. Even within disciplines, such as in biology, concepts such as evolutionary novelty are difficult to define rigorously [6,7]. In our opinion, synthesizing this vast literature (for discussion and reviews see e.g., [8–18]) with the aim of finding a simple, one-size-fits-all definition of innovation may be futile, because the development of innovation as a concept has largely occurred at the discipline level with limited cross-talk between disciplines, and different aspects of innovations are emphasized in different disciplines. Thus, regardless of how innovation is defined—mathematically, statistically or verbally—it invariably encompasses some degree of discipline- or system-specific subjectivity. Nevertheless, certain basic features common to most innovation concepts are worth highlighting (Figures 2-5, and example of winged flight in birds in Table 1).

In biology, although all innovations involve adaptive change, not all adaptations are innovations (Figure 2). This is because an innovation is a qualitative change to the phenotype² that results in a

¹ Conducted on August 15th, 2017 using the ISI “All Databases”. Search term used for each year between 2000 and 2017 was (“innovation*” and (“ecolog*” or “evolut*”)) / (“ecolog*” or “evolut*”). The annual fraction has increased at a slightly greater than linear rate between 1997 and 2017.

step departure from a recent evolutionary trend (Figure 3). The terms innovation and **novelty** are often used interchangeably in the literature, but here we make the distinction that a novelty is an individual-level concept of qualitative phenotypic change, whereas only a subset of novelties become innovations, the latter having population, community, ecosystem and evolutionary consequences. Determining what constitutes a sufficient change in the phenotype to qualify as a novelty or an innovation is a major challenge (Box 1), as is quantifying (and possibly statistically evaluating) innovation (Box 2).

A novelty stems from a series of **inventions** (mutations in biology; discoveries, ideas, or new devices in culture and technology) or recombination events to a **blueprint**, buttressed by facilitating phenotypic traits, such as **standards**. A novelty may affect structure (e.g., biochemical pathways, tissue architecture, appendages), and/or **function** and be associated, for example, with the ways organisms acquire resources, evade predators, interact with other organisms and modify their environments through niche construction or technologies.

Although rarely investigated in detail, because a novelty balances benefits to survival and reproduction with costs due to trade-offs and initial maladaptation, the invasion fitness of a novelty may be neutral or even negative (Figure 4; e.g., horizontal gene transfer [19]). This means that some inventions never become competitive novelties (a fascinating example in technology being the Einstein-Szilard refrigerators [20]), whereas others do, but require intervening mutations or recombinations for the novelty to become refined and spread as an innovation. In contrast to the roles of selection in innovation, the implications of drift are more contentious [21,22] and require further study (see also [23]).

It is useful to distinguish two basic types of novel traits leading to innovation.

In the first, the novelty is a radical modification of an existing trait, without changing the trait's qualitative function. Here, the ecological niche is not affected, but rather the trait change results in gains in performance (i.e., efficiency and/or productivity). To become an innovation, such a trait needs to confer a fitness advantage and spread through the population (Figure 4), and in so doing impact the surrounding community or ecosystem and may create longer-term opportunities for further adaptation and innovation. In the economics and technological spheres, such innovations are often associated with the replacement or “creative destruction” of existing processes or products, and are akin to some scenarios of competitive exclusion in ecology. The novelty underlying this type

² We include heritable, non-mutually exclusive phenomena, such as behaviour, culture, niche construction and technology in our notion of a phenotype.

of innovation is typically found at lower phenotypic levels, such as a biochemical pathway permitting more efficient metabolism or tissue repair.

In the second, the novel phenotypic trait is associated with a new function or change in the ecological niche (sometimes referred to in biology as a **key innovation**, e.g., [14,24–26]). Such traits may or may not increase fitness relative to the source population, because competition between the source population and novel population may be low or non-existent. Similar to the radical modification of existing traits presented above, this type of novelty becomes an innovation if invasion fitness into the new niche is positive and the emerging population impacts the surrounding community and ecosystem. In contrast to radical modification innovations, key innovations notably create opportunities for further diversification in the new ecological niche.

These two types of novelty/innovation are not mutually exclusive: a novelty may broaden a niche (Figure 6A) rather than only intensify domination of an existing niche (Figure 6B), or create a new, distinct niche (Figure 6C). Mirroring their effects on niches, innovations also produce phylogenetic pattern. By increasing in frequency and eventually becoming common and refined, innovations can either replace previous phenotypes (Figure 7A), or they foster coexistence by enlarging the same niche and thus paving the way for further innovations and adaptive radiations (Figure 7B). Finally, some innovations derive from **exaptations** [27,28], that is, they are co-opted from traits originally associated with other functions or no function at all (Figure 7C). For example, Armbruster [29] showed how the coevolution of plant-herbivore and plant-pollinator interactions in 42 *Dalechampia* species (euphorb vines) exhibited both “transfer exaptation” (a new function replaces the original function) and “addition exaptations” (augmentation of the original function).

Importantly, whether and how fast an innovation spreads depends on the environment (Figure 5). Novelties that do not initially spread through a population may become innovations at some later time (“latent innovations”), either when additional mutations or recombination events occur, or when the environment becomes favourable (Figures 2, 5).

The scope of innovation and the innovation ecosystem

Historically, the study of innovation as a stand-alone concept is often associated with human society, culture, and technology. Research topics range from the evolution of important technologies like hafting and fire, to the social transition of hunter-gatherers and the more sedentary agriculturalists who domesticated animals and plants [30], to the growth of cities and states, and the development of an immense array of technologies [31–35]. Indeed, niche construction, the manipulation of the

environment resulting in increased prospects for survival and reproduction, is a recurring theme that bridges innovative phenomena in biology and social sciences [36,37]. Whereas most if not all innovations stemming from human activity can be interpreted as forms of niche construction, only a subset of those in biology fit this definition.

Although innovation has been (arguably) a less dominant theme in biology compared to the social sciences, the related concept of novelty was an important topic of discussion during the Modern Synthesis, and both innovation and novelty have garnered increased attention over the past few decades. Innovations in biology are often gauged in terms of their transformative effects on form and function. The most revolutionary include transitions in individuality [38] and fundamental adaptations to the environment [39]. Some innovations are polyphyletic (e.g., the “minor-major” transition of multicellularity [40], others are monophyletic (e.g., photosynthesis), whereas others—particularly in the human sphere—are more challenging to accurately determine in terms of spatial and temporal origins [41]. Cultural innovations in humans and in other animals include the ability to use (tools) or modify the environment [42], specific (social or asocial) behaviours [43], and adornment that influences mating success [44]. Moreover, several studies have investigated the tendency to innovate itself as a trait (with little supporting evidence, [45,46]), or as a correlate of either life history traits such as maximum life span in birds [47], or cognitive traits such as brain size in birds and primates [48,49].

These and other general phenomena hint at an important feature of innovations: they usually involve multiple levels of organization [16,50–52]. Examples include an enzyme’s newly acquired ability to catalyse a chemical reaction that allows an organism to survive in a new environment [16], gene expression changes that help generate novel tissues which provide a quantitative advantage for development [53], or the metabolism and musculature supporting the function of a new and advantageous body structure, such as a limb or wing, which may help in locomotion [54]. Moreover, in being a qualitative departure from a previous state, an emerging novelty will have consequences for the functioning and fitness contributions of existing traits, meaning that organisms harbouring such a novelty will be under selection at the loci of other traits to accommodate the novelty as it spreads (Figure 4).

A useful way to understand these multiple levels of organization and their environmental interactions is as comprising an **innovation ecosystem**. Table 1 presents a highly simplified representation of the biological levels at which inventions, novelties and innovations operate in the innovation ecosystem of winged flight in birds. Winged flight in birds emerged as an innovation in their reptile ancestors, ultimately contributing to taxonomic diversification in the Aves [55,56]. For

flying animals such as bats and birds, wings were derived from forelimbs, and thus the innovation is not the *de novo* emergence of a trait, but rather the radical modification (exaptation) of an existing trait. For wings to be an innovation supporting bird flight, it is necessary that (i) wings specifically fulfil the proximal function of generating lift for flight, (ii) flying individuals have the scaffolding (e.g., musculature, energy allocation, cognition) required for flight, and (iii) the trait complex depicted in Table 1 is maintained by selection. Thus, gliding species such as certain squirrels and snakes do not fit this definition since they do not possess appendages that enable uplift, but neither do kiwi birds, which have useless wings. Ostriches can fly very short distances, but differences in flying abilities among them probably are either not selected or under weak selection. Albatrosses, on the other hand, have built on the innovation of wings through adaptations permitting flight over thousands of kilometres without landing, in great part due to behavioural aerodynamics (using wind updrafts). Determining whether a phenotypic trait is an innovation based on the presence/absence or quantitative criteria alone is difficult, because the trait itself may not be specific to the function being innovated and vice versa [17]. Thus, birds may use their wings for one or more of several functions in addition to flight, including flap-running, paddle-swimming, thermoregulation, brooding, and displays [54].

The roles of evolution and ecology in innovation

Whereas the basis of evolution and its importance in biology can be traced back more than 150 years [1], foundations in culture [57,58], economics [59], and technological change [34,60,61] are much more recent. Although there is a discipline-specific, historical component to the integration of evolutionary thought in studying innovations, we claim that our limited understanding of innovation ultimately derives from the complexity of the underlying processes (Figure 1).

At a coarse scale, biological evolution (heritability, mutation, recombination, drift and selection) has analogues in culture and technology. Even if operational in broadly similar ways across these disciplines, there are contrasts at finer scales in how different steps of the evolutionary process operate. This system/process-level specificity is associated with substantial scientific challenges, such as for example the identification of heritable information [62], understanding the roles of simple and complex cognitive and social processes [18] in cultural and technological systems, and assessing the extent to which biological evolution is in any way “goal oriented”. Regarding the latter, insofar as some sexually reproducing organisms exhibit mate choice, they influence the identity of their mate and thus indirectly, which genetic material is given an opportunity to recombine and help generate their offspring. Although this process may generate novelty in sexually

selected characters (e.g., peacock's tails), evidence is limited as to whether it accelerates natural selection in the short term [63], or facilitates phenotypic novelty in the longer term [64].

Evolution is the exploration of the possible, which leads to the to-be possible. This exploration, however, occurs in a space subject to constraints, which affect the emergence of novelties and the speed at which they may become innovations (Box 3). The origin of a novelty may require multiple iterations in the generation of inventions and recombinants and the retention of novelties (see also e.g., [65] for why single mutations are unlikely to produce complex adaptations), whereby intermediates either initially persist without changing appreciably in frequency (e.g., the Dykhuizen–Hartl effect [66]), or are positively selected and increase in frequency until the novel trait is fully formed and spreads through the population [67–69]. For example, Blount and colleagues [67] experimentally demonstrated how multiple clades of *E. coli* persisted for over 10,000 generations before a citrate metabolism trait arose in one lineage through the capture of a promoter exapting a previously silent duplication of the citrate transporter. Wallbank and colleagues [69] showed that introgression between lineages of *Heliconius* butterflies can generate novel colour patterns based on the recombinatory shuffling of cis-regulatory modules.

Ecological interactions and the environment impact survival, reproduction and dispersal, and may play a key role in the transition from novelty to innovation. A good example is the competition among technologies that serve the same purpose, such as transportation. Invented by 1834, electric cabs looked to outcompete horse-drawn cabs at the turn of the 20th century, but after a period of national and international expansion they failed (and so did the whole electric car industry) and by 1930 were outcompeted by internal combustion engine vehicles. This event was not only due to the quality of the technology itself, but also to insufficient environmental conditions, and in particular to battery limitations and the lack of electric infrastructure in the form of central stations [70]. Interestingly, the same technology re-emerged in California during the 1990s due to an environmental factor (air pollution); as the Zero Emission Vehicle Mandate required major auto companies to make available zero emissions vehicles [71]. But again electric vehicles failed, this time due to reasons including lack of customer interest, competition with other industries, and insufficient cooperation with key technological developers in the battery sector. More recently, the environmental context has become favourable for electric vehicles, both due to concerns about climate warming and the longer charge period and lifespan of electric batteries.

Overview of the theme issue

The idea for this collection of reviews, perspectives and original research stems from an interdisciplinary workshop entitled “Origins of Novelty in Biological, Social and Technological Systems: Towards a General Theory of Innovation”, held at the Santa Fe Institute in October 2014. It was clear from the workshop that the field is ready for synthesis, and that a reasonable step forward is to centre this synthesis in the biological sciences, with bridges to culture and technology. Box 4 and the discussion below summarize important topics addressed by contributions to this special issue, and their promise for future research.

Searching for and discovering innovation

A central theme linking the contributions to this theme issue is how innovations, which appear *a priori* unlikely or infeasible, can originate. Wagner [72] aims to address this problem by connecting evolutionary biology to information theory. Classical population genetics focuses on genotypes and the information encoded therein, but more recent work highlights the importance of phenotypes as gatherers and processors of environmental information [73]. Wagner employs information theory to quantify the information content of a phenotype and to investigate the feasibility of acquiring or “discovering” novel and beneficial phenotypes. He develops a metric of the information change associated with a new phenotype (see also Box 2), and illustrates its use in the context of DNA duplication (one route to more evolvable genotypes and a mechanism for exaptation), new transcription factor binding sites on DNA (resulting in new gene regulation and new phenotypic traits), and genes encoding biochemical reaction networks that transform environmental nutrients into biomass (e.g., amino acids and nucleotides). A limitation of this framework is that very large numbers of individuals may need to be sampled in order to estimate phenotypic information content and its change associated with novel phenotypes. Wagner proposes to mitigate this problem by using sequence data sampled from evolution experiments to quantify information differences between phenotypes. Although this approach also has limitations, for example, if a novel phenotype is highly information-rich, or requires many mutational steps to be “discovered”, Wagner shows that current technology suffices to quantify phenotypic information gain if the number of individuals sequenced from a population is sufficiently large relative to the amount of genetic variation in the population. In addition, Wagner suggests that the information-theoretic framework can address the broad question of what makes a system evolvable, by positing that evolvable phenotypes have low information content. Quantifying evolvability can help answer important questions about the rates at which species diversify (see also [26]), and about the related concept of the open-endedness of evolution in exploring spaces of possible adaptations.

With the exception of a handful of well-studied model systems, most involving microbes (see e.g., [74]), and inferences linking major changes in phenotypic traits and phylogenetic structure (reviewed in [14]), we know little about *how* evolution brings about structural/functional novelty and innovation. The question is whether the evolutionary searches of the adjacent possible described by Wagner [72] typically describe more attainable, but less revolutionary innovations than many of those observed over macroevolutionary time, which could involve families of adaptations and innovations bundled into a single phenotypic feature (e.g., bird wings, see Table 1). Erwin [75] discusses this important topic, starting with an overview of the intellectual history of “spaces”, two of the most intuitive being how the states of different genes or different phenotypic traits in an individual are associated with fitness. But the metaphor of spaces extends to ecological strategies or “ecospaces”, and relations between phenotype and function. Erwin develops the idea that a static predetermined landscape of how evolution could proceed is a considerable oversimplification of how many novelties and innovations occur. He argues that over macroevolutionary time scales, adaptive multidimensional surfaces change in topology and new dimensions are added and (these or others already existing) potentially lost. Moreover, the topology of many spaces is likely to be non-Euclidian, meaning that probabilities of shifting from A to B some topological distance away, could be complex, and even change during the macroevolutionary process. Changes to topology are a form of *a priori* blind “construction”, in that contingency in population states and environments provides the fuel for generally unpredictable changes in fitness landscape topology, including trade-offs between phenotypic traits. Erwin summarizes the importance of construction versus search in three points. First, topologies are complex, such that, locally, they are knowable and searchable, but as the space becomes more distant and less defined it is unlikely that search algorithms apply. Second, spaces evolve. Third, novelty and innovation alter spaces and generate new spaces. Erwin wonders whether novelty and innovation are space-topology specific, but notes that the pervasive observation of phenotypic convergence between otherwise independent taxa suggest that topological constraints exist and, as such, innovation is not (entirely) open-ended. More research is needed to investigate the implications of topological construction.

There are considerable challenges in evaluating competing hypotheses to explain macroevolutionary patterns in innovation. Rabosky [26] addresses some of the main issues in statistically evaluating the impact of key innovations on adaptive radiation. Key innovations are important testing grounds for innovations more generally, since in opening a new ecological space, the former are a bellwether for the rates and extent of adaptive radiation (e.g., [76]). The expectation is that ecological opportunity is created when a new adaptive zone is opened, and innovations (e.g., functional novelties) are one possible source of that opportunity [14]. Rabosky evaluates innovations on phylogenetic trees, and begins by briefly reviewing the large literature on phylogenetic inference and the interpretation of

innovations. A persistent problem is the circularity of the concept (key innovations occur when traits permitting invasion are obtained) and consequential difficulties in testing it. An alternative is to view the key innovation as an evolutionarily successful trait that results in increased diversification rates. Rabosky argues on the contrary that differential rates of lineage diversification should not be used to evaluate the existence of key innovations. If species richness is largely regulated by diversity-dependent (equilibrial) mechanisms, then there is little theoretical justification for linking innovations to faster diversification. This harkens to the idea that speciation generally entails both reproductive isolation and changes to the ecological niche (e.g. [77]); opening up a new niche (a key innovation) could facilitate the total number of new species, but does not necessarily increase the rates at which the species are formed. Rabosky argues that most tests of the predictions of key innovation have serious limitations, a central one being the low information content of many time-calibrated phylogenetic trees. He concludes that future work should focus on ecological and evolutionary mechanisms in generating macroevolutionary patterns and put less weight on oversimplified hypotheses.

Challenge and opportunity

The contributions to this theme issue highlight the fundamental importance of scale in innovation. Scale in evolution is evidently spatial and temporal, but more generally it characterises the information stored and transmitted over networks. Information is in the genotype and in the phenotype, but also, as Wagner [72] relates, in the environment. The concept of information is a calculus. Information is *differentiated* in microevolutionary time through mutation, recombination and selection, and *integrated* in macroevolutionary time when living systems change in size and complexity. This raises the intriguing question of how the rate, magnitude and nature of innovations change as a system evolves from inception to maturity, and then possibly to senescence, decline and death (see [78]). West and colleagues [79] consider the inception of what is arguably the first major transition in life -- heredity -- and more specifically how membrane replication in protocells is an important step towards the emergence of nucleic acid blueprints and more complex cellular structures. Most theory regards RNA as the key initiator of heredity in biology. But as West and coworkers argue there are some practical difficulties in heredity 'jump-starting' with RNA. Rather, innovations associated with the emergence of nucleic acids were possibly preceded by an innovation of membranes themselves as the blueprint of protocellular reproduction and inheritance. Here, the genotype is in many respects also the phenotype. The authors present an evolutionary, computational model based on the biochemistry of some of the earliest cells [80]. Leaky fatty-acid vesicles grow and reproduce based on positive feedbacks emerging from the chemical dynamics of proton

gradients across the membrane, in interaction with mineral catalysts (FeS crystals), amino acids and fatty acids in the outer and inner environments. Even this conceptually simple, empirically-based model is complex, and although data for parameter value estimates is either rudimentary or lacking, the canonical values used are plausible: when sufficiently high catalytic rates and tight amino acid binding constants are assumed, the protocells grow and reproduce. As the system evolves based on selection for larger quantities of organics inside the protocell, the likelihood of the next novelty—RNA heredity—becomes feasible. Once RNA and polymerase enzymes emerge, selection shifts in favour of a trade-off between replication speed and growth, avoiding parasitic collapse. This study highlights the pervasive observation that more complex, sophisticated levels of individuality are more likely to obtain and (generally) perform better if cheaters are prevented, kept at bay, or eliminated.

Arguably, one of the most fundamental forms of innovation is the transition from autonomous individuals to the coordinated cooperating collective and to the new integrated individual [81]. Ratcliff and colleagues [82] consider how the evolution of collective life cycles could be associated with transitions to higher level individuality. A major obstacle to transitions to higher-level individuality is the difficulty with which lower level autonomy is lost, reflected by defection and freeloading. Interestingly, even when a transition is achieved, lower-level autonomy is never completely relinquished, as evidenced for example, in cancers [83]. Key to how life cycles select for higher-level dominance is the extent to which life cycle behaviours create variability within versus between collectives. Greater heritable variation between groups compared to within groups favours cooperation and transitions to higher-level individuals [84]. Life cycles that reproduce through a single cell bottleneck and subsequently develop clonally are thus the most likely route to multicellularity. Ratcliff and colleagues review the life cycles of key systems, including *Pseudomonas fluorescens* biofilms, snowflake yeast, volvocine algae, and choanoflagellates as examples of different stages of transitions in individuality. The authors use mathematical models to compare and contrast the propensity for different life cycles to produce a transition by assessing the likelihood that a beneficial mutation affecting lower- and higher-level fitness would spread in the population. Previous work identified ‘ratcheting mutations’ (beneficial to collectives but deleterious to single cells) as those most likely to transfer command to the higher-level individual; here the authors show that these mutations should spread most quickly when multicellular individuals develop clonally and the life cycle lacks a persistent unicellular phase. Interestingly, the transition in the cases of contingent multicellularity mentioned above each require only a single mutation, suggesting the ease at which the initial novelty can emerge, which would most likely be built-upon by a battery of further genetic changes to achieve the obligate multicellular individual.

The study by Ratcliff and colleagues shows the complexity of innovations leading to multicellular emergence in the face of cheats. Cheating can take a number of non-mutually exclusive forms including: not executing a cooperative function, not contributing to the public good, or abandoning the group. But, in leading to what amounts to competition or parasitism, cheating separates a population into two or more populations, one of which is coordinated and cooperative, and the other (s) that may form a single population of autonomous individuals, or break-up into a heterogeneous ensemble of lineages or quasi-species. A key expectation is that both the cooperative “host” and the cheating “parasite” will evolve (and possibly co-evolve). This opens the possibility that some adaptations in cooperators and cheaters will entail qualitative novelty and ultimately emerge as innovations. Aktipis and Maley [83] explore the routes to and maintenance of multicellularity, and draw parallels between innovations in cellular systems and those in human society. Although the analogies remain to be investigated in detail, there is appeal in the basic insight that similarities exist between relinquishing autonomy to form complex, cooperative structures such as multicellular organisms, and in complying with norms, morals, rules and laws in human society. Aktipis and Maley discuss how the tension between cooperation and cheating in multicellular organisms leads to innovations in the host, such as programmed cell death and immune systems that protect against disease from within and disease caused by other organisms. Moreover, innovations may emerge in cellular cheaters, such as invasive neoplasms (cancer), examples including evading the immune system, adapting to and changing the microenvironment, and dispersing to colonize new, hospitable tissues and organs [85]. Similar reasoning applies to visitors or residents in the organism, such as beneficial, neutral or pathogenic species and strains in the microbiota [86]. The authors conclude that insights into how cellular societies innovate so as to protect themselves could be translated into medical approaches that improve human health.

Social cheating as a form of parasitism is an example of a more general manifestation of ecological abundance: where there are resources to consume, there will be consumers; where there are living organisms to predate or parasitize, there will be predators or parasites. The natural question is to know how hosts avoid the negative fitness effects of parasites, and how parasites can counter any such adaptations in the host. There is a considerable empirical and theoretical literature on antagonistic coevolution (e.g., [87,88]), but the origins of new adaptive strategies still remain unclear. Fortuna and coworkers [89] investigate this question using self-replicating computer programs (i.e., digital organisms) that interact and evolve in a user-defined computational environment. This approach has proved very useful for understanding evolutionary and coevolutionary processes [90,91]. The authors find that when host resistance traits emerge additionally from non-adaptive origins (i.e., exaptations), coevolution leads to complex and phenotypically diverse networks of interacting hosts and parasites. The resulting coevolutionary

outcome not only is predicted to increase population size and thereby facilitate additional adaptations and innovations, but also increases the persistence of entire communities. Interestingly, innovation mediated through exaptations may scale up to generate novel network structures that promote community persistence. These novel structures can be interpreted as forms of niche construction, and in a sense are innovations themselves.

Transmission, selection and construction of novelty

The two most discussed routes to innovation are *de novo* construction of a qualitatively new phenotypic trait and exaptation of such a trait through gene duplication or the modification of single non-functional or functional genes [15]. There is however another, oft neglected, mechanism in biology, and in culture and technology: the introduction of novelty from another population or another species, and the diffusion of novelty between individuals within a population. The importance of horizontal gene transfer or HGT has been recognized since the 1950s, stemming from its role in the transfer of antibiotic resistance, but it is only recent that an appreciation for its diversity, complexity and importance has emerged. A defining characteristic of many prokaryotes is the fuzziness of the species concept. This is largely due to their ability to transfer and accept genetic material between closely and distantly related individuals, but also between what we would consider to be different species [92]. Accepting genetic material implies that -- at least sometimes -- there is a fitness benefit that maintains the character in the lineage, but also that other life forms or mobile genetic elements such as phages and plasmids benefit from this permissivity on the part of their hosts. Hall and colleagues [74] explore how the diverse battery of HGT mechanisms contributes to the introduction and diffusion of novelties in bacteria. Hall and coworkers take significant strides towards an evolutionary framework for how HGT has been so successful and effectively conquered many conceivable routes towards expression and carriage in the recipient individual. Unique here is that the would-be innovation is likely to have been of adaptive significance (and possibly an innovation) in the donor species or lineage. The authors make the important point that due to the multitude of traits under selection in HGT, notions of the boundaries of what is an organism can become complex. In the context of innovation, the question is whether the novelty is shared between the transferred element and the donor, a sort of mutualism, which under certain environmental conditions can turn the relationship into conflict, more resembling parasitism. In either mutualistic or parasitic scenarios, there will be selection on the interacting entities to enhance or restrict subsequent transfer events, opening a world of possibilities of how HGT impacts other life-history traits, creates ecological opportunity resulting in adaptive radiations, and more generally how we view parasitism and mutualism as engines of novelty and innovation.

Horizontal information transfer such as that occurring in HGT is akin to the social transfer of information in multicellular animals. Social species span the gamut from microbes to men, but it is in the latter and in non-human animals where the transmission of novel information is best understood [18,93,94]. Specifically, a defining behaviour in many animal species is their ability to learn from others (social learning) and in so doing, incorporate the novelty (and the diffusion of the innovation through the population). However, the importance of network structure and social learning in the diffusion of innovations is difficult to assess. This is in part because agents may also learn asocially through trial and error [95]. Hoppitt [96] assesses methods for characterizing how an innovation diffuses through a social network of non-human animals when individuals can learn from others or, rather, learn through trial and error. The problem is that most past analyses have assumed basic one on one interactions, and have not developed more sophisticated tools for analysing more realistic social networks. Hoppitt evaluates an approach called Network Based Diffusion Analysis (NBDA) which can be used to a) detect the action and strength of social transmission relative to asocial transmission; and b) determine the typical pathways for diffusion of innovations in populations of animals. Hoppitt assesses what types of network should be used in an NBDA in order to accomplish each of these two goals. One problem encountered in such analyses is that the data may contain biases and noise. Hoppitt investigates different network types, among them observation networks, where social transmission can be inferred if the order of individual observation predicts the order of diffusion, and association networks where the probability of transmission is expected to correlate with the association time. He finds that these two network types are robust to bias and error in parameters. However, numerous other challenges remain, important among them being network-specific interpretations of social learning strength in the diffusion of innovations.

Many cultural variants achieve appreciable population frequencies without any apparent selective effect [97,98]. Examples in present-day humans include fads, fashions, adornment and first names. Defining characteristics of such cultural variants include their rapid emergence, spread, and decline, coexistence with alternative variants, and their promotion via the copying or the emulation of prestigious individuals [99]. One hypothesis to explain their near-neutrality, is that the present-day manifestations of these behaviours reflect evolutionary mismatches with what were more important phenomena in our distant past, and that the background behaviours promoting them have persisted. This does not preclude that the mechanisms responsible for their dynamics function the same way today as they did in the distant past. O'Dwyer and Kandler [23] explore the dynamics of what would appear to be a trait with no effect on survival or reproduction -- baby's names -- with the objective of determining the extent to which transmission might follow neutral or non-neutral processes. Bentley and coworkers [100] previously showed a power law distribution of newborn names, with an exponent that depends on invention rate and total population size. O'Dwyer and Kandler derive

an analytical approximation for this progeny distribution under neutrality and show that the distribution of names over an interval of intermediate abundances shows an exponent $-3/2$, but this exponentially declines at and beyond sufficiently abundant names. Maximum-likelihood estimates of the neutral parameter allow for direct application of the theory to data. Moreover, the authors show how selective differences between names, in form of pro- and anti-novelty bias, can be modelled and applied to a data set of newborn names in Australia. They find that the empirical patterns are best described by anti-novelty selection against inventions before they reach appreciable frequencies, but once they do, selection is relaxed and names interact in a neutral manner. These results have potential implications for how marker information (i.e., neither too common, nor too unique) is achieved in the human population. Furthermore, the authors show that analyses based on only the most common cultural variants can lead to misleading inferences about underlying transmission processes.

Two defining characteristics of humans are the complexity of their innovations and the remarkable diversity of their innovation toolbox. Innovation complexity and diversity reflect cumulative culture, that is, building culture over lifetimes and through generations. Whereas models and data indicate the probable routes of cumulative culture [101], less is known about how culture forms within the individual. Building culture during a lifetime requires repeated cycles of individual learning (a form of invention) and copying others (e.g., parents, peers, and prestigious individuals). A critical period in endogenizing is childhood. McGuigan and colleagues [102] review the growing literature on the significance of childhood in cumulative culture, and identify the underlying “dual engines” as invention and copying/transmission. The authors then present a study of children in which the subjects were free to invent, rather than have adult models introduce inventions. The authors focus on the scenario where the origin of certain inventions that contribute to cumulative culture occur during childhood [103]. The experimental design is complex, similar in spirit to an ethological field study. Despite inherent limitations in interpreting these kinds of controlled but complex experiments, the study reveals that social learning can facilitate more cumulative innovation than asocial learning, that higher level problem solving was more likely following success on a simple problem in a series, and that cumulative success could be driven both by the challenges of ecological loss of existing solutions and by the involvement of occasional superior innovators (older children). The broader picture is that humans, and ostensibly certain other primates, may be adapted to experiment and selectively transmit successful outcomes, providing a basis for the exaptation or amelioration of existing behaviours and the emergence and spread of novelties that become cumulative cultural innovations.

Interacting with, constructing and destructing the environment

The abilities of life forms to generate inventions, refine novel phenotypic traits, and diffuse some of these to become innovations are, sometimes, innovations themselves. Cognition and information processing is a vast space for such innovations. Dukas [104] provides an overview of the foundations of cognition and associated innovations leading to ever-greater complexity, particularly in mammals. An important theme in the development of cognition is the perception of danger (e.g., temperature, predators) and opportunity (e.g., resources), in particular information gathering and transmission in a social environment. A basic form of information gathering found in single cells, from bacteria to vertebrate immune systems, relies on receptors and responses, both expressed via gene networks. These mechanisms, although rapid, are limited in the range of environmental responses they can accommodate. A major innovation in animals was the advent of the nervous system, which promoted more effective environmental sensing and inter-individual communication, and further innovation enabled capacities for information storage and retrieval. The advent of learning and long-term memory required the employment of existing standards, and in particular, biochemical chains and changes in gene expression. Learning and memory, in turn, provided the basis for further behavioural innovations and in particular, social learning. Thus, each successive innovation has either incorporated or complemented previous cognitive innovations. Dukas relates how social learning would have been selected in taxa with repeated interactions between individuals and long life spans. This highlights a unique aspect of social and individual learning: expertise. Expertise is how experience (through improved skills and increased knowledge) improves the performance of complex tasks. Once social learning was established, there would have been significant selection pressure to adapt it to complex social and asocial environments. Language fills this gap, and produces new opportunities and challenges that result in further adaptations for improved cognitive ability (e.g., [105] and (its correlate) further innovation [47]. More research is necessary, particularly in understanding how evolution underpins innovation epochs in cognition and expertise, and how these employ automated and plastic responses.

The evolution of ever more sophisticated cognition in response to environmental opportunities and challenges is a prime example of how phenotypic traits diversify and complexify in form and function. Signalling (including language) and social learning would have had major consequences for how well organisms could cope with and exploit changing environments. One of the most fundamental ways in which this is accomplished is through altering the environment: niche construction. Niche construction is a powerful conduit of adaptation and innovation (e.g., [106]). However, niche construction is not limited to the extra-organismal environment--it can involve the organism's phenotype itself, through for example, "phenotypic accommodation" [106,107].

Arguably, the main distinction between the (classic conception of) the organism and its environment is that the former is an autonomous, reproducing entity. Beyond this, there may or may not be a disjunct in how information is stored and transmitted between an organism and its environment [108]. Niche construction is therefore an extension of the phenotype, subjected to selection, and manifests in gene-culture coevolution [109]. Allaby and colleagues [30] review one of the most fascinating forms of niche construction: domestication. Briefly, one species selects for sought-after traits in another, especially predictability, value and yield, and in so doing the former evolves through the development of management techniques and technologies. Although domestication and agriculture in particular occur across a broad range of taxa (slime moulds, snails, beetles, termites, ants), nowhere are they more diverse and complex as in the human population. Allaby and coworkers relate how true domestication results from directional selection on major traits, whereas the specific forms of agricultural traits in crop improvement or selection for particular varieties are often idiosyncratic to specific needs or environments. The authors discuss the well documented example of cereals, such as wheat and barley, where archeobotanical evidence suggests that morphological change occurred over thousands rather than hundreds of years, indicative of generally weak selection, but not incompatible with periods of strong selection due to environmental influences, social conditions, and prevailing technology. Allaby and colleagues evaluate this hypothesis using a combined model-data analysis of the fossil record of crop domestication to predict periods where human-driven selection in several cereals was particularly strong, and estimations of when the earliest selection for domestication began. They find that selection is indeed generally weak, and that periods of stronger selection may occur in parallel with technological innovations such as sickle technologies. Additionally, when many traits are under selection and no two are necessary for crop improvement, selection tends to be diluted on most traits and over most time periods. The authors relate how environmental and cultural contingencies were crucial to domestication rates and particular sought-after traits. Similar to other cultural and technological innovations (e.g., [108,110,111]) it appears that sufficient human populations sizes would have been necessary for cereal domestication and production innovations to obtain.

The potential for biological evolution ultimately derived from mutation. Because many if not most mutations have negative impacts on fitness, genomes have adaptations to control mutation. The stochastic nature of mutation means that their appearance (i.e., nearly neutral or beneficial mutation) depends on population size. Although controversial, this same dependence – large population size – has been hypothesized to favour cumulative cultural evolution [112]. Fogarty and Creanza [113] review the literature, which suggests that this process operates in food producing societies but not in food gathering societies, the latter of which depend more on environmental risk. The authors develop a model to investigate the independent and interactive influences of population size and

environment on cultural accumulation in the form of tools and technologies. They assume that innovation is primarily driven by environmental challenge, but that innovations are to some extent environment-specific, meaning that innovations are potentially gained and lost when populations migrate or environments change [41,114,115]. However and importantly, those populations that construct their environments (e.g., building shelters, domesticating plants and animals and associated agriculture and husbandry) buffer themselves from environmental vagaries, and population size will dominate environmental contingency in driving innovative cultural accumulation. Taken together this harkens at predictions of evolutionary theory whereby adaptation to harsh or variable environmental conditions may be achieved by increased mutation rates or phenotypic plasticity, whereas adapting to long-term predictable environmental trends depends on occasional beneficial germ line changes (mutation), which become more probable with population size [116].

How novelty manifests itself in terms of phenotypic traits, functions and fitness depends on where we look in the innovation ecosystem, the time frame in the emergence and development of the innovation, and the prevailing environmental conditions. Innovations may be beneficial for one species and detrimental for other species, as for example, an innovation permitting a host to better resist its parasite, although as shown by Fortuna and coworkers [89] the precise effects can be complex. More generally, an innovation may be detrimental to individuals, populations or ecosystems in several non-mutually exclusive ways. First, an initially beneficial innovation may be expatiated or co-opted to become a detrimental one, as in the case of dynamite invented for mining but subsequently then used for artillery. Second, an innovation may outcompete existing phenotypes, resulting in their demise or extinction (“creative destruction” in economics and technology). Third, the innovation may have negative externalities, such as pollution produced by combustion engines. And fourth, in favouring population growth, the innovation may result in overexploitation of resources and the tragedy of the commons. Weinberger and colleagues [78] consider innovation in the human population and how it can sustain growth or rather result in population collapse or even extinction. They model how innovation increases the flux of ecosystem services, which boosts population size and results in further innovation and population growth via cumulative cultural evolution. A key point underscored by the authors is that innovations can also have social and environmental costs, which limit population growth [117]. The authors find that continued innovation and population growth is only possible if the positive externalities of the innovations are sufficient, which allows for a large stock of technologies. When externalities are sufficiently negative, the population can only persist, albeit at lower numbers, if the stock is reduced to a minimum. Finally, the model shows that population collapses are possible in-between these two extremes, and these further depend on the minimum standard of technology humans are willing to

accept. This study suggests that the coevolutionary dynamics between population and innovation critically depend on the positive or negative externalities of innovations and on the changing minimum technological requirements of populations.

Concluding remarks

Innovation research encompasses a vast spectrum of phenomena, spanning the biological, cultural and technological sciences. This special issue takes modest steps in surveying and investigating the scope of interesting problems surrounding innovation, and yields a number of insights that will fuel future directions. The conceptual frameworks, mathematical and computational models and experiments in this special issue support the view that only a small number of key mechanisms may be necessary to understand innovations. Nevertheless, robust tests are elusive, particularly for innovations manifesting over long time periods. In this regard sufficiently rich data can reveal macroevolutionary patterns through, for example, ancient DNA analysis [118]. At the other extreme, the recent explosion of experimental evolution [119–121] and ever-increasing sophistication in behavioural studies [18] have important roles to play in scientifically evaluating competing hypotheses--depending on the system--over time scales amenable to many research teams. Mathematical and computational models will be central in evaluating candidate processes driving innovation regardless of time scales.

Despite our suggestion that contributors to this special issue adhere to a common definition of the term “innovation”, there were notable contrasts. These spanned the gamut from single quantitative changes to the phenotype through to qualitative novelties requiring multiple mutations and recombinations. All had in common either some form of phenotypic novelty, or a major step in the efficiency or productivity of the execution of a function. This state of affairs reflects a combination of contrasts in perspective of where adaptation stops and innovation begins, and differences in the complexity of the topology of evolutionary spaces on the path to innovation. We view this as an enriching, challenging reality of the current state of the field.

The contributions to this special issue highlight the intricacy of the innovation ecosystem, which consists of networks of phenotypic traits on different scales, associated changes in behaviour and function, performance and fitness, and current and future impacts on the surrounding community and ecosystem. Clearly, developing a constellation of theories for such multi-layered systems will be a daunting challenge and insights into how the complexity of novel traits limits their occurrence and influences their evolvability [122] will be key to theoretical developments. Given these current lacuna it is not surprising that innovation largely remains an *a posteriori* assessment of change and

its impact. Future study should identify the eco-evolutionary milestones preceding and predicting innovations.

In closing, we believe that innovation processes in biology, culture and technology have a small set of key features in common. The main defining contrast appears to be the dynamics and complexity of sensory-cognition-communication interactions (Figure 1). In this regard, we claim that these disciplines are not as distinct as they may appear, but rather they form an overlapping continuum. The moon-shot is to understand how the central features drive innovation in all living systems, paving the way for a general theory.

Acknowledgements

We thank the authors for their hard work and the quality of their contributions to this special issue, and the many external reviewers who provided constructive feedback. We would also like to thank Jennifer Dunne, Doug Erwin, Stuart Kauffman, Hanna Kokko, Manfred Laubichler, Jose Lobo, Doyle McKey, John Miller, Rolando Rebolledo, Deborah Strumsky, Peter Turchin, Jorge Velasco-Hernandez, and Andrew Whiten for their support and discussions, Helen Eaton for advice, the contributors to this special issue for their comments on this introductory paper, and to the Santa Fe Institute for facilitating our discussions over the past several years.

BOX 1. Sorites paradox

Much of our understanding of innovations is based on descriptive, conceptual frameworks. An important problem of many conceptual frameworks is encapsulated in the Sorites paradox, where the categorical labelling of a state is subjective, yet different grades of the (subjectively) labelled state are quantitative measures themselves (e.g., [123]). For example, the determination of baldness in humans has no objective threshold as measured by the number of hairs on the scalp; however, a male with fewer hairs per unit scalp area could be said to be balder than someone with more hairs. The Sorites paradox highlights why some qualitatively new phenotypic traits are deemed “innovations”, and it highlights the role of consensus and subjective judgment in this labelling. It raises the unsolved question of how or whether relative levels or magnitudes of innovation (marginal to transformational) can be scientifically distinguished from one another (see Box 2).

BOX 2. Statistical detection of innovation?

The very definition of new, novel, never before seen, makes most (if not all) innovations unknowable before they occur, or increasingly knowable (but still probabilistic) as candidate inventions emerge and novelties begin to spread. Relevant notions of feasibility and probability have been conceptualized as the “actual and the possible” [124] and the “adjacent possible” [125]. Wagner [16] establishes a rigorous definition of morphological novelty based on mechanisms leading to departures from homologous phenotypic characters (see also [50]).

Recent computational and theoretical modelling work has addressed numerous themes relating to innovation, including patterns generated by the process of technological evolution [126], distinguishing novelty [127], quantifying the magnitude of innovation [128], measuring the time to attain an innovation [129], detecting innovation as revealed by power law distributions of activities as proxies for inventions [130], and predicting innovations from the adjacent possible [131]. In the context of macroevolution, several interrelated approaches to assessing innovations (“key innovations”) have been proposed (reviewed in [26]; for adaptive radiations, see review in e.g., [14,76]). For example, Heard and Hauser [24] proposed a two part test for “key innovations”, whereby (1) an ecological/functional change in a taxon is associated with increased speciation or decreased extinction rates compared to a sister taxon, and (2) a number of innovative and sister clades are treated as independent observations. Similarly, Bond and Opell [132] proposed three criteria for a key innovation: the trait must (1) be present in two or more organisms and inherited exclusively from their common ancestor; (2) be functionally advantageous; and (3) be capable of

contributing to adaptive change. Rabosky argues that components of these and other approaches are fraught with conceptual issues and/or methodological problems (see also [11]).

Based on more recent work and on some of the contributions in this volume, we propose the following complementary criteria to identify key innovations. *Criterion 1*: A gain in phenotypic information or complexity. The gain can, in principle, be quantified using information theory [133] (see also [72]). This criterion aims to exclude adaptations that result from a loss of traits and thus a loss of phenotypic complexity [10]. *Criterion 2*: The altered or new phenotypic trait is associated with one or more measures of increased performance or novel function (e.g., flight that boosts hunting efficiency, predator escape, and/or mating number or quality), and positive relative fitness (if in same niche) or positive absolute fitness (if invading a new niche). *Criterion 3*: The growth of the population harbouring the novelty is associated with significant community and ecosystem impacts and (particularly for key innovations) in the longer term, further innovation and/or adaptive radiation of the innovated lineage. In the spirit of Figure 3, we suggest that these three criteria can each be assessed statistically as (significant) deviations from prevailing trends. Nevertheless, given difficulties in obtaining sufficiently rich data to conduct such tests (e.g., [72]), we expect that their application will be difficult if not impossible for many systems.

BOX 3: The limits to innovation

Scaling theory in biology and technology offers several examples of contrasts between different organisms or products that -- although apparently substantially different -- are nevertheless variations on the same theme. In the accompanying figure, we show two cases. The first involves metabolic rate. Even though a unicellular organism is clearly different than an elephant, both actually satisfy the same statistical scaling law between mass and metabolic rate. Metabolic innovations, however, are strongly suggested by the visible discontinuities (changes in the intercept) that define qualitatively different groups (poikilotherms and homeotherms) (*cf* discontinuities portrayed in Figure 3). The second example involves motors, both biological and engineered, and their force output. Here, the constraints appear more severe, resulting in that the maximum force output generated by a fly's muscles satisfies the same constraint as the force output of a jet engine. Thus, the "space of the possible" in this relationship is constrained by simple, general rules stemming from the fundamental laws of chemistry, physics and biology.

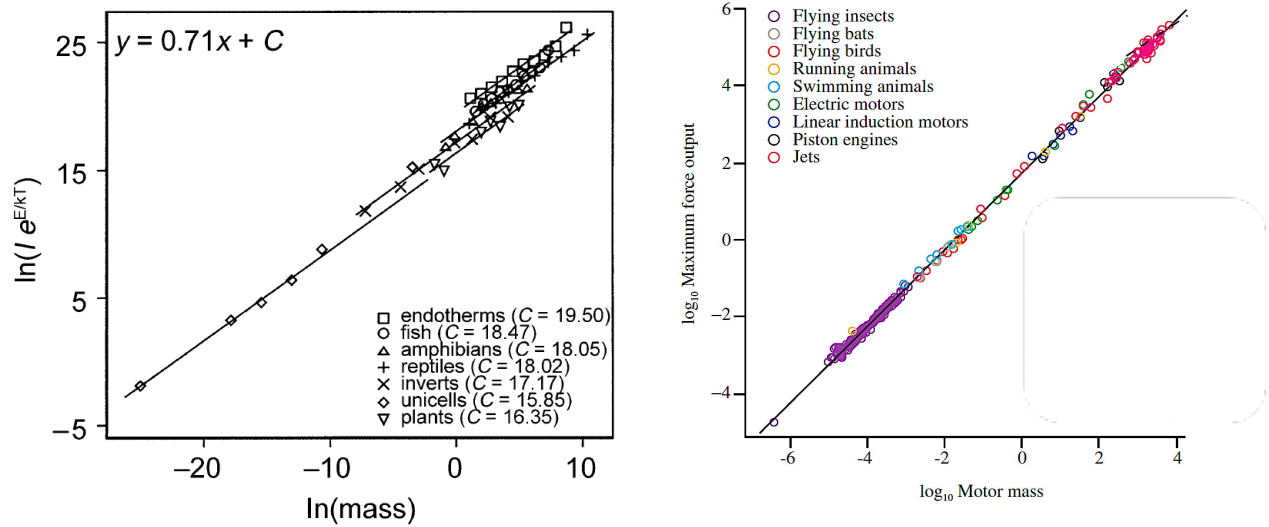

Figure in Box 3

Legend for figure in Box 3. Scaling in biology and technology. Panel A shows relationship between temperature-corrected metabolic rate, $\ln(IeE/kT)$, measured in watts, and body mass, $\ln(M)$, measured in grams. Variables are M , body size; I , individual metabolic rate; k , Boltzmann's constant; T , absolute temperature (in K). E is the activation energy (after [134]). Panel B shows the scaling of force output for different biological and engineered motors (after [135]).

BOX 4: The importance of innovation

A deeper understanding of innovative change will be built on a research program integrating behaviour, ecology, evolution, environment, network theory, and information theory. This program is important for several reasons and generates numerous challenging questions.

- **Understanding innovation contributes to crystallizing notions of the predictability of evolution.** How predictable (or inevitable) are innovations in the biological and in the cultural and technological realms? This is important since a major distinction between biology and culture/technology is the latter's (apparent) goal-oriented, rapid generation and filtering of ideas and inventions (the Sensory and Cognition box in Figure 1; see also [136]). Nevertheless, there is evidence that many innovations in culture/technology stem from serendipitous events [137,138]. In biology, novelties are similarly difficult if not impossible to predict before their building blocks begin to emerge [75,121].
- **Innovations and population growth are expected to be mutually reinforcing.** Features of a population including its size, social interactions, and established standards [110,138,139] influence the probability of innovation. Innovation may foster ecological opportunity, which, in turn promotes population expansion and adaptive radiation [14,140]. In cultural evolution where this phenomenon is also reasonably well studied, population growth may promote cultural evolution [141] and demographic change [142]. Therefore, population growth and innovation are expected to be mutually reinforcing [78,113,130,143,144].
- **Innovation is often associated with solving problems and/or realizing opportunities.** Problems or challenges occur within the current niche, and include unfavourable abiotic conditions and difficulties in obtaining resources. Opportunities require operating in other niches, and include more favourable abiotic conditions and the availability of novel resources (for biology and technology see [145]; for behavioural innovations see [146,147]). To the extent that unsolved problems limit population size (and the associated likelihood of inventions), does this also stymie innovation (see e.g., [148])?
- **Studying innovation is central to understanding the diversity and complexity of life.** Could an increase in diversity associated with innovations result in the saturation of niches and in ever-fewer opportunities for further innovation, or in innovations of progressively smaller magnitude? Or rather, is innovation continual and open-ended [22]? For example, could an increase in diversity caused by innovations result in the saturation of niches and in ever-fewer opportunities for further innovation, or in innovations of progressively smaller magnitude? Are environmental disturbances and/or population extinctions necessary to 'reset the clock', providing adaptive space for new innovations? Does innovation simplify system structure in some contexts, and complexify it in

others? Under what conditions does organism complexity [149] or system robustness [150] affect innovation?

- **Innovation instructs on associations between adaptation and fitness.** Mean population fitness is expected to increase for adaptations to the current ecological niche, but mean fitness may increase, decrease or remain unchanged when adapting to a new habitat (for discussion and examples, see [151]). In producing a (considerable) rewiring of phenotypic traits and being constrained by tradeoffs, do innovations decrease certain measures of fitness? Headway in understanding innovation in response to challenges with novel carbon substrates has recently been made using an experimental evolution approach [152].
- **Innovations influence existing trade-offs and may create new ones.** Tradeoffs occur when there is competition involving: phenotypic traits, gene expression, hormones and signalling molecules, and resource allocation [153]. In rewiring the phenotypic traits of an organism, or influencing levels of selection [82], will the emergence of a novelty also shift traits along existing trade-off surfaces or change the shapes of trade-offs themselves? This can be viewed metaphorically as altering the ruggedness and shifting fitness peaks on a fitness landscape, or adding new trait dimensions to a multi-dimensional landscape [154].
- **Innovations may have negative externalities and evolve in terms of their function and impact on the environment.** An innovation's functions may evolve and diversify, a prime example being domestication [155]. Such innovations can have net benefits, but also negative externalities. Examples include the effects of domestication on farm animal well-being and associated land use changes (see e.g. [93], and theoretical development in [78]). In addition, the same innovation can have different uses, such as the exaptation of fertilizer components for making explosives [156]. Vermeij and Leigh [145] argue that human-driven innovative systems are more prone to negative externalities than are natural systems.
- **A general theory of innovation will identify processes that unite biological, cultural and technological spheres.** Many authors have compared and contrasted evolutionary frameworks for innovation between biology, culture and technology (e.g., [34,37,139,145]). Is there a level of resolution at which all innovations follow the same basic rules? Or rather, are the apparent differences between innovations in generational (slow evolutionary) systems and intra-generational (fast) systems actually just different points along a continuum?

Glossary

Adaptation: A trait that helps an organism survive or reproduce in a given environment.

Blueprint: Stored information that interacts with the environment, resulting in a phenotype. The stored information may be transmitted from parents to offspring via genetic material or epigenetic alterations, or between individuals via horizontal gene transfer or through cultural / behavioural inheritance. Blueprints are subject to alteration (e.g., mutation) and to evolution due to random drift and selection. Examples of structures containing or embodying blueprints include DNA, brains, patents, instruction manuals, and semiconductors.

Exaptation: The modification or co-opting of an existing phenotypic trait, which may or may not have served a fitness-influencing function, into a new or radically modified trait with the same or new function.

Function: The association between a phenotype and a behaviour that influences performance and fitness. Function therefore has proximal (behaviour) and ultimate (performance and fitness) components. In the example of bird wings, proximal components include flying and paddling. Ultimate components include resource acquisition and predator avoidance.

Innovation: A qualitatively novel change to the phenotype that results in either a radical performance improvement to an existing function and spreads through the population, or the emergence of a new function and the establishment of a new ecological space (key innovation). Innovations have significant impacts on the surrounding community and the ecosystem, and in the case of key innovations, on lineage diversification.

Innovation ecosystem: The ensemble of components (DNA, molecular, cellular and tissue architectures, other complex phenotypic traits) forming an innovation, and their interactions with each other and the surrounding environment (see example of winged flight in birds in Table 1). A given component may be specific to a particular innovation, whereas other components may be associated with the innovation and to other (possibly unrelated) traits.

Invention: The appearance of a new phenotypic variant or the modification of an existing variant. The variant potentially contributes to producing a novelty. In biology, certain DNA mutations produce inventions, whereas in culture and technology inventions result from new ideas and discoveries.

Key innovation: Novel traits that promote niche expansion or the invasion of qualitatively new niches, and result in lineage diversification.

Novelty: The radical modification of an existing phenotypic trait or the emergence of a new phenotypic trait. A novelty may form the basis of an innovation if the former spreads through a population, or results in population expansion into a new ecological niche.

Phenotypic trait: Any (bio)chemical, physical, or behavioural feature of the individual, resulting from the interaction between blueprints and environments.

Standards: Specifications or properties shared by the components of a technology. Commonly applied to human technologies, the notion can also be applied to adaptations and innovations that occur in different organisms.

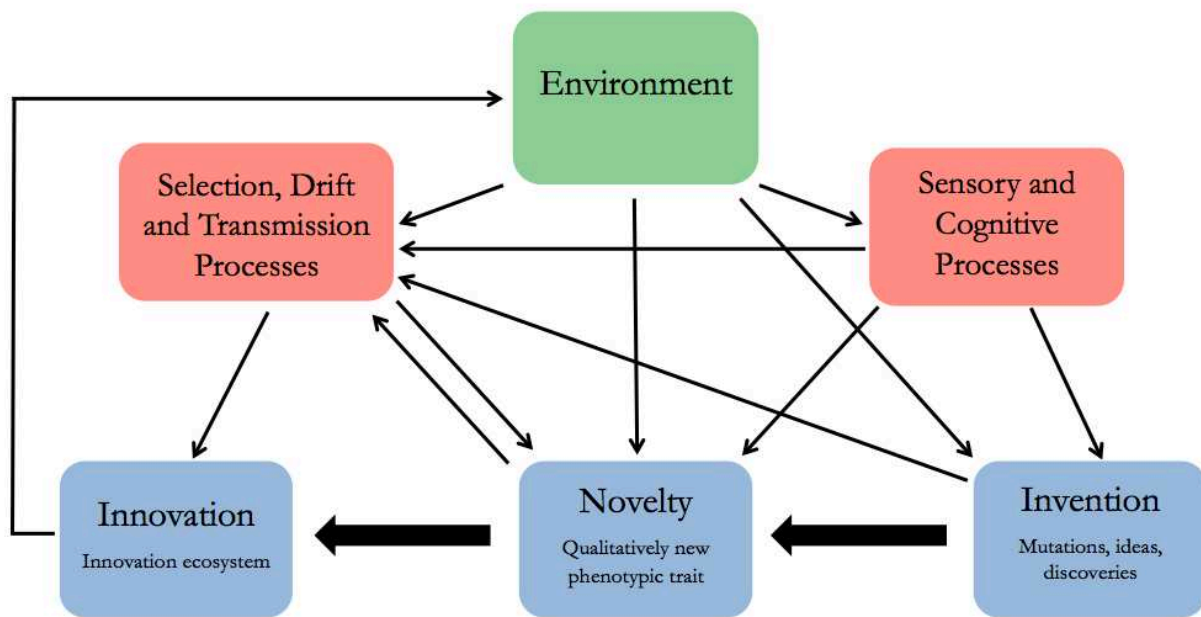

Figure 1. A simplified diagram of processes leading to innovation. Innovations are the result of inventions and recombinations that generate a qualitative phenotypic change, or a novelty, that is transmitted between individuals, and subject to selection and stochastic effects. Innovation manifests as the novelty spreads (or after it has spread), the former embodying interactions and interdependencies at various scales (i.e., the “innovation ecosystem”; see Table 1 for example of winged flight in birds). As emphasized by papers in this special issue, the environment influences the emergence of innovations, which, in turn, impact the environment. Note that the conventional notion of biological innovation (as opposed to cultural and technological) downplays the role of sensory and cognitive processes in the generation, filtering and horizontal spread of information (and possible novelties) among individuals.

		Positive fitness	
		Yes	No
Qualitative change	Yes	Innovation	Latent innovation
	No	Adaptive change	Neutral change

Figure 2. A classification of change. Most successful adaptations are not innovations (lower left), since necessary conditions for an innovation (upper left) include both a qualitative change in a phenotypic trait (a novelty) and that the novelty has positive fitness; that is it either spreads through the population (positive relative fitness resulting in competitive elimination of the ancestor) or results in the invasion of a new niche (positive absolute fitness). Some qualitative trait changes have nearly neutral or even negative fitness effects, and either persist at low frequencies (latent innovations; upper right), or go extinct and may only return if a specific mutation or recombination event occurs again, or in the realm of human technology if an invention is rediscovered and integrated into an existing process or product. See main text for discussion of additional necessary conditions for innovations.

Figure 3. Illustration of how innovations may impact the state of a population through time. In (A), the population adapts, but does not innovate. It is also possible that no adaptation occurs during certain periods or that the population maladapts (not shown). In (B), the population innovates without appreciably altering its ecological niche. Innovations (dotted segments) are infrequent step departures from the prevailing adaptive trend (solid segments). Innovations become increasingly frequent as the population grows in size (due to, for example, more mutations or more recombination events) and as the population accumulates more information (e.g., trait complexity; cumulative culture). In (C), the population innovates (dotted segments) and in so doing invades and radiates in a new ecological niche. Four such populations (or species) are illustrated here (ancestor line A, and three derived populations/species, each represented by a dashed black line followed by a solid line, the latter representing adaptation). Note that “population state” could be represented in different ways depending on the context, including population size, absolute fitness, relative fitness (selection), phenotypic complexity or cumulative culture. The trajectories presented in this figure therefore are intended to depict innovations as step departures from a trend and not a precise representation of any specific measure of population state.

Figure 4. Simplified representation of the fitness of an innovated lineage through time. Invention (e.g., mutations) and recombination may lead to a novelty, which may show an increase in fitness of novel phenotype relative to the ancestral phenotype (dashed line), no change (not shown), or a net cost (solid line). The latter may occur if major rearrangements underlie the novelty, or if environmental conditions are not favourable. To potentially become an innovation, the novelty must spread in the population, or promote population invasion into new niches, and either of these may require some combination of refinements (e.g., DNA mutations that compensate costs; ameliorations that make a technology more efficient or productive), adaptations in other phenotypic traits, and environmental change. Note that fitness may or may not eventually increase relative to the ancestral population in situations where the innovation is associated with the invasion of a new, open niche (not shown).

Figure 5. Hypothetical examples of how an environmental variable affects the spread of a novel phenotype. The interaction between the novelty (change in ancestral fitness due to the novelty) and the environment may either inhibit (latent innovation or extinction; blue shading) or promote (innovation; red shading) the spread of the novel phenotype. The lower curve shows a novelty that goes extinct unless the state of a hypothetical environmental variable is favourable. The middle curve shows a novelty that persists at low values of the environmental variable and only increases at intermediate / high values. The upper curve shows a novelty that always spreads regardless of environmental conditions.

Figure 6. Effect of innovation on niche occupation. Niche breadth before a hypothetical innovation is shown by the solid curve. In (A), the innovation is associated with simultaneous expansion (right extreme) and contraction (left extreme) of niche occupancy. In (B), the innovation permits greater efficiency and/or productivity, resulting in domination of part of the same niche (e.g., creative destruction). In (C), the innovation is associated with a shift to, and domination of, a new niche. All curves expressed as relative frequencies (niche occupancy); other competing populations not shown.

A. Creative destruction

B. Adaptive radiation

C. Exaptation

Figure 7. Hypothetical innovation phylogenies for three basic (non-mutually exclusive) scenarios. In creative destruction (A), each successive novelty occupies a single niche, and the resulting innovation competitively eliminates the previous one(s). Innovation may create opportunities for further diversification (B), whereby each successive adaptation or innovation expands the niche (e.g., bipedal posture and wings). Finally, an innovation may be exapted (C) from a previous phenotypic state, resulting either in replacement of the previous state or coexistence between the ancestral and derived states. See also Figure 3.

Table 1. Winged flight as an innovation ecosystem. This table shows multiple (non-exhaustive) biological levels of organization, how they are associated with invention, novelty and innovation, and how these associations manifest in the example of winged flight, which originated in dinosaurs and persists to this day in their avian descendants with numerous adaptive and novel modifications [157,158]. “Winged flight” is a convenient label for an innovation, but the underlying adaptations and novelties form a trait complex, and together with environmental interactions, comprise an innovation ecosystem. All components of this innovation ecosystem (e.g., developmental pathways, tissue architectures, and behaviours) contribute to winged flight. These components may themselves be novelties, and may be singular to wings and flight, or they may have been co-opted or modified from other trait complexes (see e.g., [159] for the origins of feathers). In table below, x (?) indicates that the indicated entity does (may) affect the associated biological level.

BIOLOGICAL LEVEL	Genes	Molecules Cells Tissues	Organs Systems Appendages	Individual	Population	Community Ecosystem Diversification
ROLE IN INNOVATION ECOSYSTEM	<i>Encoding</i>	<i>Expression and Development</i>	<i>Physiological or Ecological Function</i>	<i>Performance</i>	<i>Selection and Evolution</i>	<i>Ecological impact and Adaptive radiation</i>
INVENTION	x	x	?	?		
NOVELTY	x	x	x	x	?	
INNOVATION	x	x	x	x	x	x
EXAMPLE OF WINGED FLIGHT IN BIRDS	Genes encoding the development and expression of bird appendages and wings in particular	Development and expression (tissue structure and metabolism) produce and maintain wings and their substructures (muscles, feathers, cartilage)	Wings enable propelled flight	Flight enables escape from antagonists, local foraging, long distance displacement	Enhanced performance increases fitness and representation of novel trait in future generations	Adaptive radiation in birds. Ecological success of innovated species may result in ecosystem impacts
